Method for specifying accuracy and cross-calibration of Video Quality Metrics (VQM)

CAUTION !

PREPUBLISHED RECOMMENDATION

This prepublication is an unedited version of a recently approved Recommendation. It will be replaced by the published version after editing. Therefore, there will be differences between this prepublication and the published version.

FOREWORD

The International Telecommunication Union (ITU) is the United Nations specialized agency in the field of telecommunications. The ITU Telecommunication Standardization Sector (ITU-T) is a permanent organ of ITU. ITU-T is responsible for studying technical, operating and tariff questions and issuing Recommendations on them with a view to standardizing telecommunications on a worldwide basis.

The World Telecommunication Standardization Assembly (WTSA), which meets every four years, establishes the topics for study by the ITU-T study groups which, in turn, produce Recommendations on these topics.

The approval of ITU-T Recommendations is covered by the procedure laid down in WTSA Resolution 1.

In some areas of information technology which fall within ITU-T's purview, the necessary standards are prepared on a collaborative basis with ISO and IEC.

NOTE

In this Recommendation, the expression "Administration" is used for conciseness to indicate both a telecommunication administration and a recognized operating agency.

Compliance with this Recommendation is voluntary. However, the Recommendation may contain certain mandatory provisions (to ensure e.g. interoperability or applicability) and compliance with the Recommendation is achieved when all of these mandatory provisions are met. The words "shall" or some other obligatory language such as "must" and the negative equivalents are used to express requirements. The use of such words does not suggest that compliance with the Recommendation is required of any party.

INTELLECTUAL PROPERTY RIGHTS

ITU draws attention to the possibility that the practice or implementation of this Recommendation may involve the use of a claimed Intellectual Property Right. ITU takes no position concerning the evidence, validity or applicability of claimed Intellectual Property Rights, whether asserted by ITU members or others outside of the Recommendation development process.

As of the date of approval of this Recommendation, ITU [had/had not] received notice of intellectual property, protected by patents, which may be required to implement this Recommendation. However, implementors are cautioned that this may not represent the latest information and are therefore strongly urged to consult the TSB patent database.

**Method for specifying accuracy and
cross-calibration of video quality metrics (VQM)**

Summary

Video quality metrics are intended to provide calculated values that are strongly correlated with viewer subjective assessments. This Recommendation provides methods for curve fitting VQM objective values to subjective data in order to facilitate the accuracy calculation, an algorithm to quantify the accuracy of a given VQM, a simplified root mean square error calculation to quantify the accuracy of a VQM when the subjective data has roughly equal variance across the VQM scale, and a method to plot classification errors to determine the relative frequencies of “false tie”, “false differentiation”, “false ranking”, and “correct decision” for a given VQM.

Source

ITU-T Recommendation J.149 was prepared by ITU-T Study Group 9 (2002-2004) and approved under the WTSA Resolution 1 procedure on March 2004.

1 Scope

Video quality metrics are intended to provide calculated values that are strongly correlated with viewer subjective assessments. This Recommendation provides:

- (a) Methods for curve fitting VQM objective values to subjective data in order to facilitate the accuracy calculation and to produce a normalized objective value scale that can be used for cross correlation between different VQMs;
- (b) An algorithm (based on statistical analysis relative to subjective data) to quantify the accuracy of a given VQM;
- (c) A simplified root mean square error calculation to quantify the accuracy of a VQM when the subjective data has roughly equal variance across the VQM scale;
- (d) A method to plot classification errors to determine the relative frequencies of “false tie”, “false differentiation”, “false ranking”, and “correct decision” for a given VQM.

The methods specified in this Recommendation are based on objective and subjective evaluation of component video such as defined by Recommendation ITU-R BT.601 using methods such as described in ITU-R BT.500. A data set for a VQM will consist of objective values and mean subjective scores for a variety of motion video sources (SRC) processed by a variety of hypothetical reference circuits (HRC). An example of such a data set is given in ITU-T COM9-80-E, the Video Quality Experts Group phase 1 final report (See Appendix A).

The methods specified in this Recommendation are directly applicable to a defined data set as described above. For measurements not specifically part of the data set the methods specified in this Recommendation provide a reasonable estimate of accuracy and cross-calibration for applications that can be considered to be similar to and within the scope of the defined data set.

The methods specified in this Recommendation are appropriate for use in combination with other statistical calculations in order to evaluate the usefulness of a VQM. Informative information regarding the use of the methods is presented in Appendix A. A complete verification process by suitable independent laboratories is required for a VQM to be considered for inclusion as a normative part of an ITU-R recommendation.

3 Accuracy of a VQM

In order to use an objective video-quality metric (VQM), one must know whether the score difference between two processed videos is statistically significant. Hence, a quantification is needed of the accuracy (or resolving power) of the VQM. To visualize this resolving power, it helps to begin with a scatter plot in which the abscissa of each point is a VQM score from a particular video source (SRC) and distortion (Hypothetical Reference Circuit, or HRC), and the ordinate is a subjective score

from a particular viewing of the SRC/HRC. Each SRC/HRC combination (associated with a particular VQM score) contains a distribution of mean subjective scores S based on a number of viewers, which represents (approximately) the relative probabilities of S for the particular SRC/HRC combination. The resolving power of a VQM can be defined as the difference between two VQM values for which the corresponding subjective-score distributions have means that are statistically different from each other (typically at the 0.95 significance level).

Given this qualitative picture, two metrics for resolving power will be described in this section, each one useful in a different context. The metrics are described in Sections 3.3 and 3.4. Also, in Section 3.5, a method is described for evaluating the frequencies of different kinds of errors made by the VQM. As an example of implementation of all the methods, a computer source code in MATLAB (The Mathworks, Inc., Natick, MA) is provided in Appendix B.

3.1 Nomenclature and coordinate scales

Let each SRC/HRC combination in a data set be called a “situation”, and let N be the number of situations in this data set. A subjective score for situation i and viewer l will be denoted as S_{il} , and an objective score for situation i will be denoted as O_i . Averaging over a variable such as viewer will be denoted with a dot in that variable location. For instance, the mean opinion score of a situation will be denoted as $S_{i\bullet}$. The subjective-score statistics from each pair (i, j) of these situations are to be assessed for significance of VQM difference, and then used to arrive at a resolving power for the VQM difference, as a function of the VQM value.

Prior to any statistical analysis, the original subjective mean opinion scores $S_{i\bullet}$ are linearly transformed to the interval $[0, 1]$, defined as the *Common Scale*, where 0 represents no-impairment and 1 represents most impairment. If *best* represents the no-impairment value of the original subjective score and *worst* represents the maximum impairment of the original subjective scale, then the scaled scores $\hat{S}_{i\bullet}$ are given by

$$\hat{S}_{i\bullet} = \frac{S_{i\bullet} - \text{best}}{\text{worst} - \text{best}}.$$

Next, the VQM scores are transformed to this Common Scale as a byproduct of the process of fitting the VQM scores to the subjective data, which will be discussed in the following section.

3.2 Fitting VQM values to subjective data

Fitting removes systematic differences between the VQM and the subjective data (e.g., dc shift) that do not provide any useful quality discrimination information. In addition, fitting all VQMs to one common scale will provide a method for cross-calibration of those VQMs.

The simplest method of data fitting is linear correlation and regression. For subjective video quality scores, this may not be the best method. Experience with other video quality data sets¹ indicates chronically poor fits of VQM to subjective scores at the extremes of the ranges. This problem can be ameliorated by allowing the fitting algorithm to use non-linear, but still monotonic (order-preserving), methods. If a good non-linear model is used, the objective-to-subjective errors will be smaller and have a central tendency closer to zero.

¹ See section 13.1, ITU-T COM 9-80-E, Rapporteur Q11/12 (VQEG): Final report from the video quality experts group on the validation of objective models of video quality assessment, June 2000.

Nonlinear methods can be constrained to effectively transform the VQM scale to the [0, 1] Common Scale. Besides improving the fit of data with a VQM, a fitting curve also offers an additional advantage over the straight-line fit implied by the Native Scale (i.e., the original scale of the VQM): the distribution of objective-to-subjective errors around the fitted model curve is less dependent on the VQM score. Of course, the nonlinear transformation may not remove all the score dependency of objective-to-subjective errors. To capture the residual dependence, it would ideally have been useful to record objective-to-subjective error as a function of VQM value. However, typical data sets are too small to divide among VQM bins in a statistically robust way. Therefore, as will be clear in Section 3.3, a sort of average measure over the VQM range is computed.

Figure 1 shows the improved fit of model to data incurred by transforming the objective scores using a fitting function. It can be seen that, besides improving the fit of data with VQM, the curve also offers an additional advantage over the straight-line fit implied by the Native Scale: the distribution of model-to-data errors around the fitted model curve is less dependent on the VQM score.

We denote the original (Native Scale) objective scores O_i , and the Common Scale objective scores as \hat{O}_i . A fitting function F (depending on some fitting parameters) connects the two. The function used to fit the objective VQM data (O_i) to the scaled subjective data (\hat{S}_i) must have the following three attributes: (a) A specified domain of validity, which should include the range of VQM data for all the situations used to define the accuracy metric; (b) A specified range of validity, defined as the range of Common Scale scores (a sub-range of [0, 1]) to which the function maps; and (c) Monotonicity (the property of being either strictly increasing or strictly decreasing) over the specified domain of validity. Of course, the fitting function would be most useful as a cross-calibration tool if it were monotonic over the entire theoretical domain of VQM scores, covered the entire subjective Common Scale from 0 to 1, and mapped to zero the VQM score that corresponds to a perfect video sequence (no degradations, hence a null distortion). However, this ideal may not be attainable for certain VQMs and function families used to perform the fit.

One possible family of fitting functions is the set of polynomials of order M . Another is a logistic function with the form

$$\hat{O}_i = a + b / \{1 + c(O_i + d)^e\},$$

where a , b , c , d , and e are fitting parameters². A third possibility is a logistic function with the form

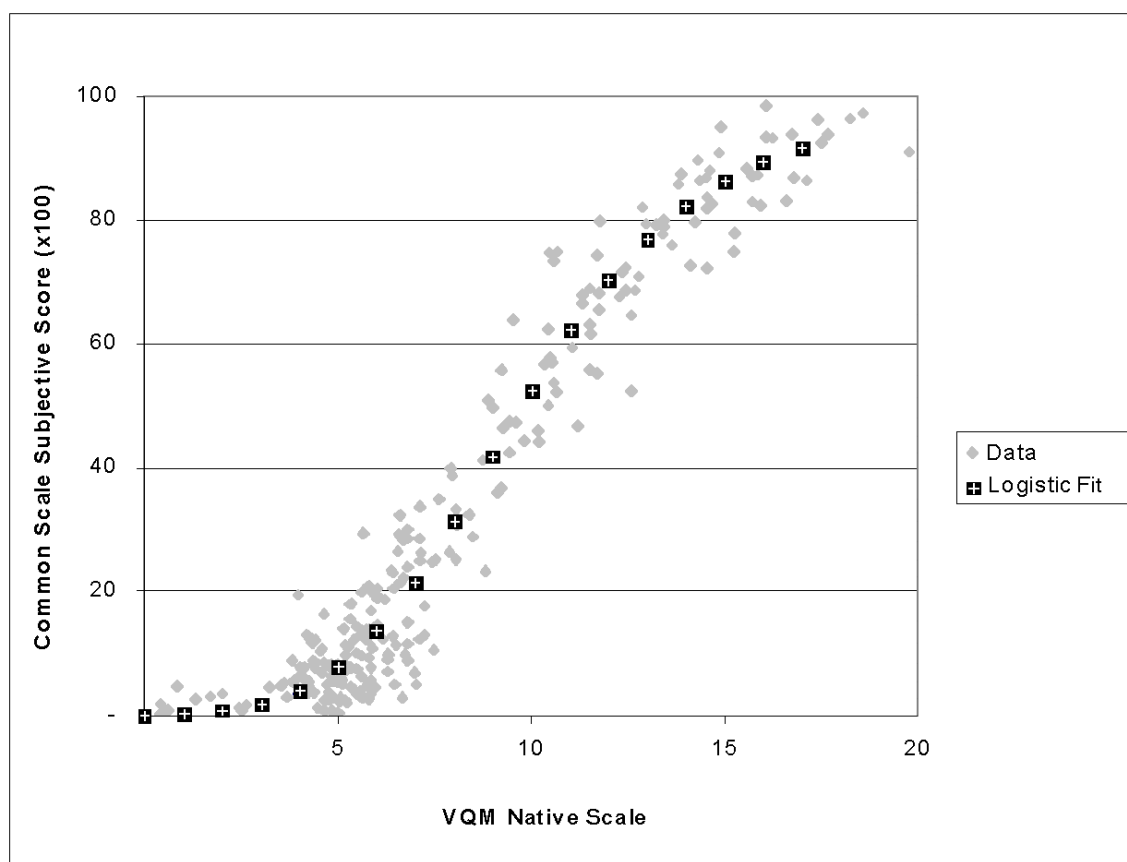

$$\hat{O}_i = a + (b-a) / \{1 + \exp[-c(O_i - d)]\},$$

where a , b , c , d are fitting parameters and $c > 0$.³ For convenience, we call these logistic forms Logistic I and Logistic II, respectively. The MATLAB code in Appendix B instantiates only a polynomial fit. Appendix C discusses possible methods of data fitting using the logistic functions. The selection of a fitting-function family (including a priori setting of some of the parameters) depends on the asymptotic (best and worst) scores of the particular VQM.

² ITU-T COM12-60, Evaluation of new methods for objective testing of video quality: objective test plan, September 1998.

³ A modified version of this logistic function was used in sections 6.2.3 and 6.2.4 of ITU-T COM 9-80-E, Rapporteur Q11/12 (VQEG): *Final report from the video quality experts group on the validation of objective models of video quality assessment*, June 2000. The modification accounted for differences in variances of the subjective ratings.

FIGURE 1
Improved fit of data to VQM by mapping VQM to Common Scale

The number of degrees of freedom used up by the fitting process is denoted by D . For example, if a linear fit is used, $D = 2$ since two free parameters are estimated in the fitting procedure. The fitting function that transforms objective VQM to the Common Scale is reported to facilitate industry comparison of two VQMs. Whether a 5, 4, 3, or 2 free parameter fit is appropriate depends on the particular dataset. Care should be taken to avoid over fitting, as this usually leads to unstable and meaningless results and can often cause the fitting algorithm to fail to converge.

Once transformed to the Common Scale, any VQM can be cross-calibrated to any other VQM through the Common Scale. Representing the accuracy of a VQM in Common Scale facilitates comparisons between VQMs. Also, assuming the resolving power in the Common Scale does not vary much with the VQM score at which the resolving power is evaluated, the resolving power can be mapped through the inverse of the logistic function to the Native Scale. In the Native Scale, the ΔVQM from the Common Scale generates a VQM-score-dependent resolving power. A table or equation that provides such resolving powers (one at each VQM score in Native Scale) will have immediate meaning for users of the Native Scale.

3.3 METRIC 1. VQM accuracy based on statistical significance

We define a new quantitative measure of VQM accuracy, called resolving power, defined as the ΔVQM value above which the conditional subjective-score distributions have means that are statistically different from each other (typically at the 0.95 significance level). Such an “error bar” measure is needed in order for video service operators to judge the significance of VQM fluctuations. Commercial software to implement the resolving power statistic may not be available.

Of several possible approaches to assessing a VQM's resolving power, the Student's t -test was chosen. This test was applied to the measurements in all pairs i and j of situations. Emerging from the test are the Δ VQM (i.e., the difference between the greater and lesser VQM score of i and j) and the *significance* from the t -test. This *significance* is the probability p that, given i and j , the greater VQM score is associated with the situation that has the greater true underlying mean subjective score. Thus, p is the probability that the observed difference in sample means of the subjective scores from i and j did not come from a single population mean, nor from population means that were ordered oppositely to the associated VQM scores. To capture this ordering requirement, the t -test must be one-tailed. For simplicity, the t -test was approximated by a z -test. This approximation is a close one when the number of viewers is large, as was the case for the VQEG data set (footnote 1).

An analysis of variance (ANOVA) test might seem better than the t -test method. However, although a single application of ANOVA will determine whether a statistical separation exists among a set of categories, further paired comparisons are needed to determine the magnitudes and conditions of the statistically significant differences. Also, ANOVA assumes equal category-data variances (which may not be true). Finally, although ANOVA resides in many software packages, finding the right software package may not be easy (e.g., not all ANOVA routines will accept different quantities of data in different categories).

The algorithm has the following steps:

Step 1. Start with an input data table with N rows, each row represents a different situation (i.e., a different source video and distortion). Each row i consists of the following: the source number, the distortion number, the VQM score O_i , the number of responses N_i , the mean subjective score $S_{i\bullet}$, and the sample variance of the subjective scores V_i .

Step 2. Transform the subjective scores $S_{i\bullet}$ to Common Scale $\hat{S}_{i\bullet}$ as described in Section 3.1. The variance V_i of the subjective scores must also be scaled accordingly as

$$\hat{V}_i = \frac{V_i}{(\text{worst} - \text{best})^2}.$$

Note that transforming the subjective scores and their variances are optional. It will not change the z statistic defined below, but it may change the VQM fitting process. Next, transform the VQM scores O_i to the Common Scale using a fitting function as discussed in Section 3.2, and amplified in

Appendix C. The result of the fitting process is a set of Common Scale VQM scores \hat{O}_i . Display the coefficient values used in the fit, and also the VQM domain over which the fit was done (domain of validity).

Step 3. For each pair of distinct situations i and j ($i \neq j$), use a one-tailed z -test to assign a probability of *significance* to the difference between the greater and the lesser VQM (\hat{O}_i and \hat{O}_j , respectively).

The significance is the probability that the greater VQM score comes from the situation with the greater true underlying mean subjective score. The z score is

$$z = (\hat{S}_{i\bullet} - \hat{S}_{j\bullet}) / \sqrt{(\hat{V}_i / N_i + \hat{V}_j / N_j)}$$

and the probability of significance of the z score $p(z)$ is just the cumulative distribution function of z :

$$p(z) = \text{cdf}(z) = (2\pi)^{-0.5} \int_{-\infty}^z \exp(-z^2/2) dz.$$

Step 4. Create a scatter plot of $p(z)$ (ordinate) versus ΔVQM score (abscissa). Given N situations, record each pair (i, j) with $i > j$, record the VQM difference $\hat{O}_i - \hat{O}_j$ in a vector of length $N(N-1)/2$ called ΔVQM (with index k), and record the corresponding z score in a vector called \mathbf{Z} with length $N(N-1)/2$ (with the same index k). It is desired to ensure that $\Delta\text{VQM}(k)$ is always nonnegative, which can be ensured by definition of the otherwise arbitrary ordering of the endpoints i and j . To ensure that this is so, if $\Delta\text{VQM}(k)$ is negative, then replace $\mathbf{Z}(k)$ by $-\mathbf{Z}(k)$ and $\Delta\text{VQM}(k)$ by $-\Delta\text{VQM}(k)$.

Step 5. Consider 19 bins (indexed by m) of ΔVQM , each one of which spans 1/10 the total range of ΔVQM . The bins overlap by 50 percent. Associate ΔVQM_m with the midpoint of each bin and associate p_m with the mean of $p(z)$ for all z in bin m .

Step 6. Draw a curve through the points $(\Delta\text{VQM}_m, p_m)$, to produce a graph of p versus ΔVQM . Note that p can be interpreted as the average probability of significance.

Step 7. Select a threshold probability p , draw a horizontal line at the ordinate value p , and let its intercept with the curve of step 6 determine the threshold ΔVQM , defined as the accuracy. For an average probability of significance of p or greater, the ΔVQM should exceed this threshold. Common choices of p are 0.68, 0.75, 0.90, and 0.95.

Having found a value of ΔVQM for a chosen p , one can use it directly in Common Scale – as would be appropriate for cross-calibration in Section 4. Alternatively, for other purposes, one has the option of inverse mapping this ΔVQM value back to the Native Scale to give a Native Scale resolving power R as a function of the native objective score O :

$$R(O) = |F^{-1}[F(O) + \Delta\text{VQM}] - O|,$$

where F is the fitting function defined in Section 3.2. For the logistic functions in Section 3.2, the inverse of Logistic I is

$$F^{-1}(x) = [(1/c)(b/[x-a]) - 1]^{1/e} - d,$$

and the inverse of Logistic II is

$$F^{-1}(x) = d - (1/c) \ln[(b-a)/(x-a) - 1].$$

When $|\Delta\text{VQM}| \ll 1$, $R(O)$ can be approximated as

$$R(O) = |\Delta\text{VQM} / F'(O)|,$$

where $F'(O)$ is the derivative of F with respect to O . This approximation should suffice for most purposes.

NOTE – For the logistic functions in Section 3.2, the derivative of Logistic I is

$$F'(x) = -bce (x+d)^{e-1} / \{1 + c(x+d)^e\}^2,$$

and the derivative of Logistic II is

$$F'(x) = c (b-a) \exp[-c(x-d)] / \{1 + \exp[-c(x-d)]\}^2.$$

3.4 METRIC 2: VQM RMSE calculation

If the subjective data have roughly equal variance across the VQM scale, then a pooled estimate of variance, or resolving power, may be appropriate. As an example, we choose the root-mean-squared error (RMSE). The basic idea behind the VQM RMSE calculation is to quantify the mean squared error (MSE) between fitted objective data and corresponding subjective data. The VQM RMSE between the fitted objective data \hat{O}_i and the scaled subjective data $\hat{S}_{i,\bullet}$ is computed as

$$VQM_RMSE = \sqrt{\frac{1}{N-D} \sum_{i=1}^N (\hat{O}_i - \hat{S}_{i\bullet})^2}$$

where N is the total number of situations (equal to IJ , where J is the number of scenes and I is the number of HRCs), and D is the degrees of freedom used up by the objective to subjective curve fitting performed in Section 3.2. Commercial software to implement the classification error statistics may not be available

3.5 Classification plots

Classification errors are one way to evaluate the effectiveness of a Video Quality Metric (VQM). A classification error is made when the subjective test and the VQM lead to different conclusions on a pair of data points. This section discusses the meaning of the classification errors, in terms of the plots of subjective z score versus delta-VQM described in the main text. For the following description, we use the common $[0, 1]$ scale for both the subjective and objective scores. Here, “0” represents no impairment and “1” represents maximum impairment.

For any subjective test one can set a threshold Δz , that defines when two data points (A, B) are statistically equivalent and when they are statistically distinguishable⁴. Once this has been done, the subjective test results allow one to place each pair of data points (A, B) into one of three categories:

$$\begin{array}{llll} \Delta z_{AB} < -\Delta z & \rightarrow \text{A is better than B} & \rightarrow \text{Bs} \\ -\Delta z \leq \Delta z_{AB} \leq \Delta z & \rightarrow \text{A is same as B} & \rightarrow \text{Es} \\ \Delta z < \Delta z_{AB} & \rightarrow \text{A is worse than B} & \rightarrow \text{Ws} \end{array}$$

The abbreviations for the three categories (Bs, Es, and Ws) denote subjectively better, subjectively equivalent, and subjectively worse, respectively.

Now consider a similar threshold for VQM values, Δo :

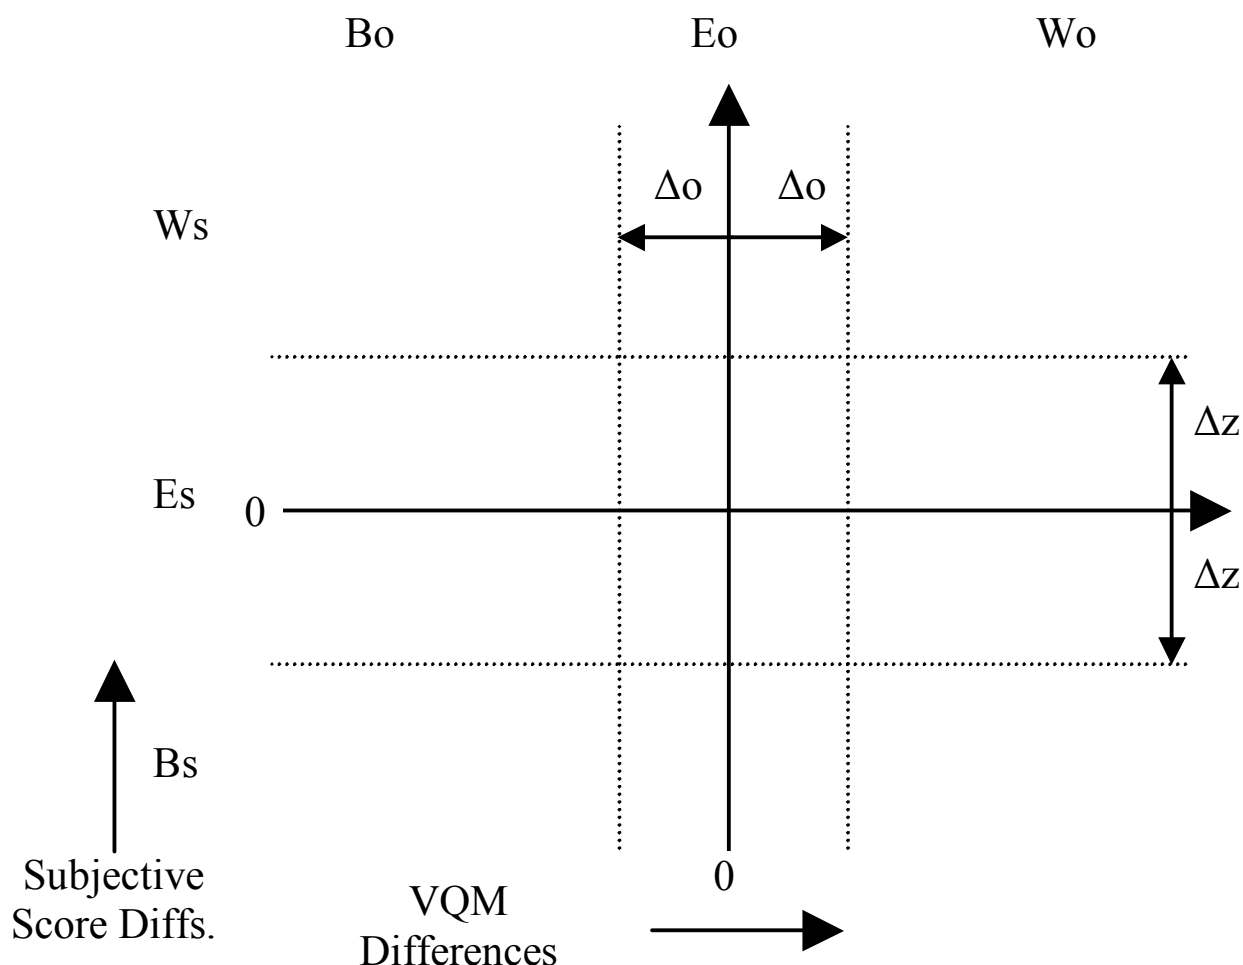

$$\begin{array}{llll} VQM(A) - VQM(B) < -\Delta o & \rightarrow \text{A is better than B} & \rightarrow \text{Bo} \\ -\Delta o \leq VQM(A) - VQM(B) \leq \Delta o & \rightarrow \text{A is same as B} & \rightarrow \text{Eo} \\ \Delta o < VQM(A) - VQM(B) & \rightarrow \text{A is worse than B} & \rightarrow \text{Wo} \end{array}$$

The abbreviations for the three categories (Bo, Eo, and Wo) denote objectively better, objectively equivalent, and objectively worse, respectively.

Since each pair of data points undergoes a three-way classification by the subjective test and a separate three-way classification by the VQM, there are nine possible outcomes. These nine outcome spaces are illustrated in Figure 2 by the broken lines in the two-dimensional space of subjective-score difference versus VQM difference:

⁴ The data points A and B actually represent sets of observations of two SRC/HRC combinations. As discussed in the main text, the quantity Δz_{AB} is the difference in the means of A and B ($\hat{S}_{A\bullet} - \hat{S}_{B\bullet}$), divided by the inferred standard deviation $\sqrt{(\hat{V}_A / N_A + \hat{V}_B / N_B)}$, where \hat{V}_A is the variance of scores from situation A, and N_A is the number of observations from situation A, etc.

FIGURE 2
Schematic classification diagram

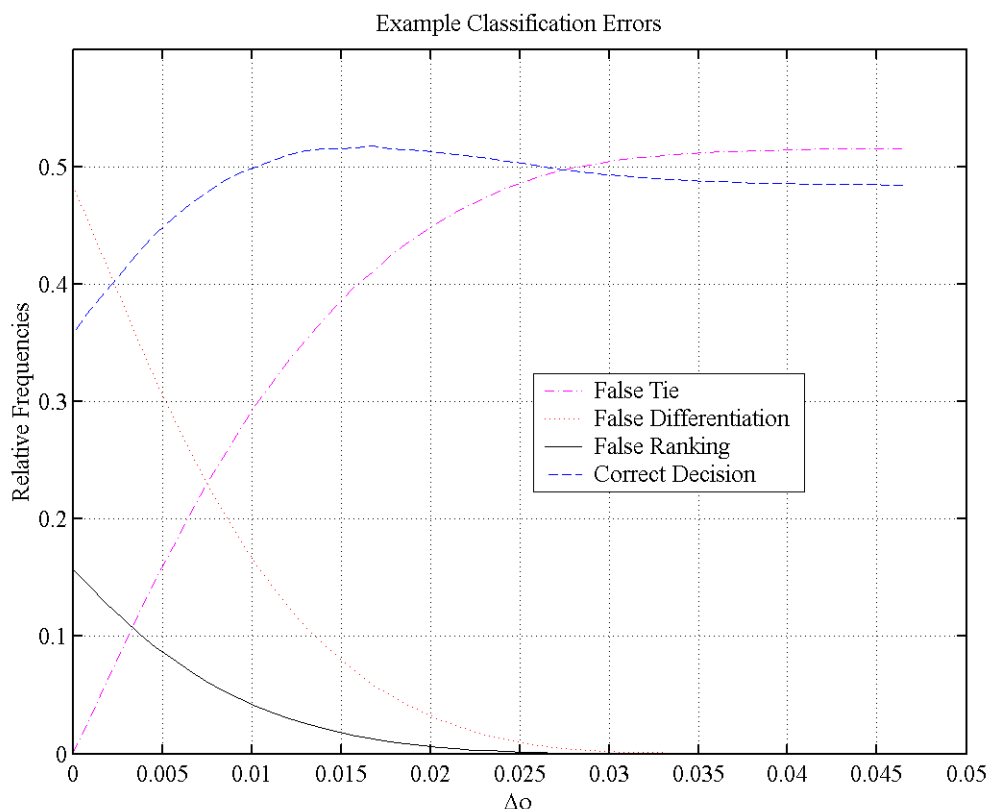

In the Table below, we label each of these nine outcomes with an eye towards answering the question “How does the VQM-based 3-way classification compare with the subjective test-base 3-way classification?”

	B_s	E_s	W_s
W_o	False Ranking	False Differentiation	Correct Decision
E_o	False Tie	Correct Decision	False Tie
B_o	Correct Decision	False Differentiation	False Ranking

Note that for three of the outcomes, the VQM classification agrees with the subjective test classification. These three outcomes are labeled “Correct Decision.” The six remaining outcomes correspond to three different types of errors that can arise when using a VQM. The false tie is probably the least offensive error. This occurs when the subjective test says two data points are different but the VQM says they are the same. A false differentiation is usually more offensive. This occurs when the subjective test says two data points are the same but the VQM says they are different. The false ranking would generally be the most offensive error. In false ranking, the subjective test says A is better than B, but the VQM says B is better than A.

For any subjective test and any VQM, we can form all possible distinct pairs of data points and count the number of pairs that fall into each of the four distinct outcome categories: Correct Decision, False Tie, False Differentiation, and False Ranking. We can then normalize by the total number of distinct pairs and report relative frequencies for these four outcome categories. In general these results will be functions of both Δs and Δo . Example results for a fictitious VQM are given in the graph below. Δz was selected to give an estimated 95% confidence in the subjective classifications and Δo is the free parameter on the x-axis of the graph.

FIGURE 3
Sample plot of frequencies of classification error

Note that as Δo is increased, the VQM will declare more and more pairs of data points as equivalent. This reduces the occurrences of false differentiations and false rankings, but increases the occurrence of false ties. As Δo goes to 0.05, the false-tie rate tends towards 0.52. At this point, the VQM is declaring all pairs to be equivalent, and in doing so the VQM is wrong 52% of the time, and correct 48% of the time. This is consistent with the fact that in this test, 48% of the pairs of data points were declared equivalent by the subjective test. One might use a graph like this to select an appropriate value of Δo . For example, one might select Δo to maximize the probability of making correct decisions, or one might select Δo to minimize some weighted sum of the error relative frequencies.

In the code that generated the above figure (part of the MATLAB code in Appendix B), the threshold used for the subjective test is `subj_th`. The threshold used for the Δ VQM, `vqm_th`, is left as a free parameter. The code plots the frequency of occurrence for the three different kinds of errors and for no error vs. `vqm_th`. An optimal value of `vqm_th` might be one that maximizes the frequency of occurrence of no error, or one that minimizes a cost-weighted sum of the errors. In general, it is likely

that false ties will be the least offensive error, false differentiations will be more offensive, and false rankings will be the worst sort of error.

NOTE – The nine outcomes and the three by three grid in (Δ VQM, subjective Z score) space is the most natural way to describe this analysis. This assumes bipolar values for Δ VQM. But the code has already taken the absolute value of Δ VQM (and replaced Z with -Z for all points with negative values of Δ VQM). This does not change the mathematics, but the more natural description of the situation is now 6 outcomes and a 2 by 3 grid. Two correct outcomes (A better than B and A worse than B) have been folded on top of each other. There are still two false tie outcomes, but only one false differentiation outcome and one false ranking outcome.

4 Cross-calibrating two VQMs

The need to relate two VQMs is met by the transformation to a Common Scale described in Sections 2.1-2.2⁵. Once two VQMs (say, VQM1 and VQM2) are transformed to the Common Scale (through an agreed-upon subjective dataset), the transformation from VQM1 to VQM2 is simply the forward transformation from VQM1 to the Common Scale and then the inverse transformation from Common Scale to VQM2. Models to be compared have to be referenced to a common dataset. In cases for which the domains or ranges of the mapping mismatch, the cross-calibration must be declared to be undefined. This Recommendation does not specify a particular common data set.

⁵ **CAVEAT. One must use caution in making inferences from cross-calibration—e.g., cross-calibration of two VQMs does not mean one of the VQMs can be substituted error-free for the other.** One reason for this limitation is that the present cross-calibration method depends on the particular subjective data that define the Common Scale. It might be argued that no subjective data are needed for a cross-calibration, and that one could connect two VQMs directly through their outputs given a particular set of inputs (trial and reference video pairs). However, no matter what set of VQM inputs are chosen for the cross-calibration, the VQMs may respond differently to some other videos. More fundamentally, even within the chosen input set, there are likely four inputs (1, 2, 3, 4) such that both VQM scores change in the same direction going from 1 to 2, but in opposite directions going from 3 to 4. Such behaviour is what makes one VQM better than another, and cannot be captured in any cross-calibration method.

Appendix A

Application of this recommendation in the evaluation and validation of proposed VQMs

(Informative)

A.1 Elements of a full VQM disclosure

Each candidate VQM must be independently validated and fully disclosed such that it could be readily implemented by someone knowledgeable in the art. The description of newly proposed VQMs should include three different datasets: (a) Test vectors to check implementation of the VQM, including video inputs and resulting VQM outputs; (b) validation/accuracy data, including subjective ratings and model outputs (spanning enough quality range to be representative of typical transmitted videos); and (c) data relating to other evaluation methods such as The Pearson linear correlation coefficient between objective and subjective scores, Spearman rank of order correlation between objective and subjective scores, and Outlier ratio. Finally, there should be descriptions of scope and limitations, accuracy, and model cross-calibration as described in subsequent sections of this Recommendation.

A.2 Scope/limitations of a VQM

The scope of a VQM can include the following elements (an illustrative list, intended neither to be prescriptive nor exhaustive): (a) The type of scene content (“signal”), e.g., high/low motion, color versus black-and-white, interlaced versus progressive. (b) The type and severity of artifacts (“noise”), driven by encoding techniques and bit rates (e.g., blurring, blockiness). (c) The viewing conditions (including viewing distance, ambient illumination, and display parameters such as gamma, brightness, and phosphor types). Each VQM should be qualitatively assessed as to the type of scene content, type and severity of artifacts, and viewing conditions under which the VQM can and cannot operate effectively. It is important to list known problem areas (such as video distortions that include dropped frames) that would otherwise not be obvious, but the scope/limitations section is not intended to be an exhaustive list.

A set of four tables should be included in the description of the VQM’s scope and limitations. The first three of these tables should enumerate all the distortions (hypothetical reference circuits, or HRCs) of the data set of the Video Quality Experts Group (VQEG), and optionally others, as follows: (a) a table of test factors, coding technologies, and applications for which the VQM has shown accuracy; (b) a table of test factors, coding technologies, and applications for which the VQM has been tested but *not* shown the accuracy specified in Section 3; and (c) a table of known test factors, coding technologies, and applications for which the VQM has not been tested, or where the VQM is not recommended. In addition, there should be (d) a table of test sequences used to determine test factors, coding technologies and applications for which the VQM has shown the accuracy specified in Section 3.

Sample Tables (a), (b) and (d) are shown below for the VQEG phase-1 full reference television (FR-TV) tests. Since these three tables exhaust the VQEG phase-1 data set, sample Table (c) would not contain any entries. The VQEG phase-2 data (ITU-T COM 9-C60-E, September 2003) has not been included since copyright restrictions prevent this data set from being generally available for VQM validation testing

BIT RATE	RES	METHOD	COMMENTS
2 Mb/s	$\frac{3}{4}$ resolution	mp@ml	This is horizontal resolution reduction only

3 Mb/s		mp@ml	with errors

Table b. Test factors, coding technologies and applications for which the VQM method has not shown the specified accuracy.

Sequence	Characteristics
Balloon-pops	film, saturated color, movement
NewYork 2	masking effect, movement
Mobile&Calendar	available in both formats, color, movement
Betes_pas_betes	color, synthetic, movement, scene cut
Le_point	color, transparency, movement in all the directions
Autumn_leaves	color, landscape, zooming, water fall movement
Football	color, movement
Sailboat	almost still
Susie	skin color
Tempete	color, movement

Table d. Test sequences used to determine test factors, coding technologies and applications for which the VQM has shown the specified accuracy.

Appendix B – MATLAB Source Code

(Informative)

Below is a MATLAB subroutine called `vqm_accuracy.m`. This version scales the subjective data to `[0,1]`, applies a polynomial fit of the objective to the scaled subjective data, calculates all the metrics, and plots the VQM frequencies of 'False Tie', 'False Differentiation', 'False Ranking', and 'Correct Decision'. It is sufficient to have Version 5.3.1 of MATLAB (1999) with the Statistics and Optimization toolboxes that are available separately. Software can also be developed that does not use either toolbox. The present code is intended as an illustrative example, and does not include all possible options and fitting functions.

Usage: At the matlab prompt, for VQM r0 type:

```
>load r0.dat
```

```
>vqm_accuracy(r0,-1,0,100,2)
```

For VQM r2, type:

```
>load r2.dat
```

```
>vqm_accuracy(r2,1,0,100,2)
```

Here, `r0.dat` and `r2.dat` are text files that contain a subset of the VQEG 525-line data. Each line in this file corresponds to a situation, and comprises an SRC number, an HRC number, VQM score, number of viewings, mean subjective score, and subjective-score variance. Once the `r0` and `r2` dat files are loaded, either form of `vqm_accuracy` may be run again.

In the first calling argument of `vqm_accuracy`, `r0` corresponds to the PSNR model in TR A3, and `r2` corresponds to the PQR model in TR A4. The second argument is 1 if the objective metric indicates worse image quality when it is larger, else the argument is `-1`. The third and fourth arguments are the nominal best and worst ratings on the native subjective scale. The final argument is the order of the polynomial to which the VQM is fit.

Source Code:

```
function vqm_accuracy (data_in, vqm_sign, best, worst, order)
% MATLAB function vqm_accuracy (data_in, vqm_sign, best, worst, order)
%
% Each row of the input data matrix data_in must be organized as
% [src_id hrc_id vqm num_view mos variance], where
%
% src_id is the scene number
% hrc_id is the hypothetical reference circuit number
% vqm is the video quality metric score for this src_id x hrc_id
% num_view is the number of viewers that rated this src_id x hrc_id
% mos is the mean opinion score of this src_id x hrc_id
% variance is the variance of this src_id x hrc_id
%
% The total number of src x hrc combinations is size(data_in,1).
%
% vqm_sign = 1 or -1 and gives the direction of vqm with respect to
% the common subjective scale. For instance, since "0" is
% no impairment and "1" is maximum impairment on the common
% scale, vqm_sign would be -1 for PSNR since higher values
% of PSNR imply better quality (i.e., this is opposite to
% the common subjective scale).
%
% mos and variance will be linearly scaled such that
% best is scaled to zero (i.e., the best subjective rating)
```

```

% worst is scaled to one (i.e., the worst subjective rating)
%
% order is the order of the polynomial fit used to map the objective data
% to the scaled subjective data (e.g., order = 1 is a linear fit).
%

% Number of src x hrc combinations
num_comb = size(data_in,1);

% Pick off the vectors we will use from data_in
vqm = data_in(:,3);
num_view = data_in(:,4);
mos = data_in(:,5);
variance = data_in(:,6);

% Scale the subjective data for [0,1]
mos = (mos-best)./(worst-best);
variance = variance./((worst-best)^2);

% Use long format for more decimal places in printouts
format('long');

% Fit the objective data to the scaled subjective data.
% Following code implements monotonic polynomial fitting using optimization
% toolbox routine lsqlin.
%
% Create x and dx arrays. For the dx slope array (holds the derivatives of
% mos with respect to vqm), the vqm_sign specifies the direction of the slope
% that must not change over the vqm range.

% This portion of the code calculates and plots the relative frequencies of

```

```

% three types of classification errors. A classification error is made when
% the subjective test and the VQM lead to different conclusions on a pair
% of data points.
%
% Background: For any subjective test, one must set a threshold that will
% determine when two results are statistically equivalent, and when they are
% statistically distinguishable. Then for each pair of data points (A,B),
% the subjective test can yield one of three possible outcomes: (1) A better
% than B, (2) A same as B, and (3) A worse than B.
%
% If we define a similar threshold for VQM values, we have the same
% situation. For each pair of data points, VQM can yield one of three
% possible outcomes: (1) A better than B, (2) A same as B, and (3) A worse
% than B. Since each pair of data points undergoes three-way classification
% by the subjective test and three-way classification by the VQM, there are
% nine possible outcomes. For three of these outcomes, the subjective test
% and the VQM agree. If we take the subjective test to be correct by
% definition, and the VQM to be under test, then we say that for these three
% outcomes, the VQM is correct. In two other cases the VQM has committed the
% "false-tie" error (subjective test says A better than B, or A worse than B,
% but VQM says A same as B). In two other cases the VQM has committed the
% "false differentiation" error (subjective test says A same as B, but VQM
% says A better than B, or A worse than B.) Finally, there are two cases
% where the VQM has performed a false ranking (subjective test says A better
% than B, or A worse than B, but VQM says the opposite.) Thus, all nine
% outcomes are accounted for. Note that a three by three grid in
% (delta_vqm, subjective Z score) space describing the above could be drawn.
%
% In the code below, the threshold used for the subjective test is subj_th.
% The threshold used for the delta VQM is vqm_th and this is left as a free
% parameter. The code plots the frequency of occurrence for the three
% different kinds of errors and for no error vs. vqm_th. An optimal value of
% vqm_th might be one that maximizes the frequency of occurrence of no error,
% or one that minimizes a cost-weighted sum of the errors. Note that in
% general, it is likely that false ties will be the least offensive error,
% false differentiations will be more offensive, and false rankings will be
% the worst sort of error.
%
% For more details, see S. Voran, "Techniques for Comparing Objective and
% Subjective Speech Quality Tests," Proceedings of the Speech Quality
% Assessment Workshop, Bochum, Germany, November 1994.
%
% Note: The nine outcomes and the three by three grid in (delta_vqm,
% subjective Z score) space is the most natural way to describe this
% analysis. This assumes bipolar values for delta_vqm. But the code has
% already taken the absolute value of delta_vqm (and replaced Z with -Z for
% all points with negative values of delta_vqm). This does not change the
% math, but the more natural description of the situation is now 6 outcomes
% and a 2 by 3 grid. Two correct outcomes (A better than B and A worse
% than B) have been folded on top of each other. There are still two false
% tie outcomes, but only one false differentiation outcome and one false
% ranking outcome.

Appendix C

Data-fitting to a common scale of VQM

(Informative)

As discussed in Section 3.2 of the main text, the objective VQM data (O_i) are mapped to a new domain $\hat{O}_i = F(O_i)$. This domain is derived by fitting O_i to the scaled subjective data ($\hat{S}_{i\bullet}$) using a family of functions F (with fitting parameters) that have the properties of monotonicity and range mapping noted in Section 5.2. The following are three alternative choices for the form of F , together with notes on data fitting using these functional forms.

C.1. Polynomial of order M. A polynomial that is fit to a set of data points is not guaranteed to be monotonic. The MATLAB optimization toolbox has a function `lsqlin` that ensures monotonicity over the extent of the data. However, monotonicity over the existing data domain does not ensure monotonicity over the entire theoretical domain (for example, 0 to infinity).

C.2. Logistic Function I. Fitting the objective VQM data (O_i) to the scaled subjective data ($\hat{S}_{i\bullet}$) can be done using a logistic function

$$\hat{O}_i = F(O_i) = a + b / \{1 + c(O_i + d)^e\},$$

where a , b , c , d , and e are fitting parameters. The fit function must be derived by nonlinear least squares.⁶ The part of the function to be used is the monotonic part for $O > -d$ (hence constrain $d > -\min(O)$), and the s-curve shape appropriate to the data fit is ensured by constraining $e > 1$.

In certain cases, at least asymptotically, the perfect score in the native-scale objective model can be made to map to zero (the best score on the subjective scale), and the worst native-scale objective score possible can be made to map to the worst subjective score (unity, on the Common Scale). For example, consider the following case: *Best objective score is zero, worst objective score is infinite*. Here zero maps to zero and infinity maps to 1, so $a = 1$ and $b = -(1 + cd^e)$, hence

$$F(O_i) = 1 - (1 + cd^e) / \{1 + c(O_i + d)^e\}.$$

⁶ Constrained least squares nonlinear curve fitting can be performed with the MATLAB function `lsqcurvefit`.

Fitting would take place on c, d, e, subject to d, e > 0.

C.3. Logistic Function II. Fitting the objective VQM data (O_i) to the scaled subjective data ($\hat{S}_{i\bullet}$) can also be done using a logistic function

$$\hat{O}_i = F(O_i) = a + (b-a)/\{1 + \exp[-c(O_i - d)]\},$$

where a, b, c, and d, and $c > 0$ (ensured by defining $c = |C|$ for real C). As with Logistic I, the fit function must be derived by nonlinear least squares⁷.

One might use this optimization in the case noted in B.2: *Best objective score is zero, worst objective score is infinite*. Here zero maps to zero and infinity maps to 1, so $a = -\exp[-cd]$ and $b = -a \exp[cd]$. Hence

$$F(O_i) = [1 - \exp(-cO_i)]/[1 + \exp\{c(d - O_i)\}].$$

Logistic Function II is also useful in the following case (which could arise when O_i is expressed in logarithmic coordinates such as decibels): *Best objective score is infinite, worst objective score is negative-infinite*. In that case infinity must map to 0, and negative infinity must map to 1. Hence $b = 0$, $a = 1$, and

$$F(O_i) = 1/[1 + \exp\{c(O_i - d)\}].$$

⁷ On p. 28 of the VQEG phase-1 final report (COM9-80-E), the initial values for the parameters were chosen as a = minimum subjective score, b = maximum subjective score, $c = 1$, and d = mean objective score. A modified version of Logistic Function II was also used that accounted for differences in the variances of the subjective ratings.
